Abstract

Objective: NEM® brand eggshell membrane is a novel dietary supplement ingredient that contains naturally occurring glycosaminoglycans and proteins essential for maintaining healthy joints. A six center, open label clinical study was conducted to evaluate the efficacy and safety of NEM® as a treatment for pain and inflexibility associated with osteoarthritis of the knee and/or hip in a European population.

Methods: Forty-four subjects received oral NEM® 500 mg once daily for eight weeks. The primary outcome measure was to evaluate the mean effectiveness of NEM® in relieving general pain associated with moderate osteoarthritis of the knee and/or hip at 10,30 and 60 days utilizing a 10-question abbreviated questionnaire based on the WOMAC osteoarthritis questionnaire.

Results: Supplementation with NEM® produced a significant treatment response from baseline at 10 days (Q1-6 and Q9) (8.6% to 18.1% improvement) and at 30 and 60 days for all nine pain-related questions evaluated (22.4% to 35.6% improvement) and at 30 and 60 days for stiffness (Q10) (27.4% to 29.3% improvement). In a Patient's Global Assessment, greater than 59% of patients rated the efficacy of NEM® as good or very good following 60 days of supplementation. Physicians also rated the treatment effective in subjects, with greater than 75% having moderate or significant improvement from baseline after 60 days. There were no serious adverse events reported during the study and the treatment was reported to be well tolerated.

Conclusions: Supplementation with NEM® significantly reduced pain, both rapidly (10 days) and continuously (60 days) demonstrating that it is a safe and effective therapeutic option for the treatment of pain associated with osteoarthritis of the knee and/or hip. Results from previous clinical studies on NEM® can likely be extended to the broader European population.

Keywords: Knee, Hip, Osteoarthritis, Eggshell membrane, NEM, Dietary supplement, Glycosaminoglycans

Introduction

Estimates of the prevalence of osteoarthritis (OA) in European populations vary widely, however a recent study [1] from a region in Spain places the prevalence of knee OA at 12.2% and that of hip OA at 7.4%. The pain associated with these maladies can be quite debilitating and sometimes severe side effects. NEM® brand eggshell membrane has been shown previously to be beneficial in the treatment of OA [12,13]. Eggshell membrane itself has previously demonstrated good efficacy in relieving pain and stiffness associated with OA of the knee in an RCT [6] and has shown similar efficacy in limited trials for other affected joints [7].

Eggshell membrane is primarily composed of fibrous proteins such as Collagen Type I [8]. However, eggshell membranes have also been shown to contain other bioactive components, namely glycosaminoglycans (i.e. dermatan sulfate, chondroitin sulfate and hyaluronic acid and keratan sulfate) [9-11]. A number of these constituents have been shown previously to be beneficial in the treatment of OA [12,13]. Eggshell membrane itself has been shown both in vitro [14] and in vivo [15] to reduce various pro-inflammatory cytokines, including interleukin-1 beta (IL-1β) and tumor necrosis factor alpha (TNF-α), two primary mediators of inflammation. A U.S. company, ESM Technologies, LLC (Carthage, MO USA), has developed methods to efficiently and effectively separate eggshell membrane from eggshells on a commercial metric-ton scale. The isolated membrane is hydrolyzed using a proprietary process and dry-blended to produce NEM® brand eggshell membrane. Compositional analysis of NEM® conducted by the manufacturer has identified a high content of protein and moderate quantities of glucosamine (up to 1% by dry weight), chondroitin sulfate (up to 1%), hyaluronic acid (up to 2%), and collagen (Type I, up to 5%).

The multi-center trial reported herein was designed to evaluate the acceptability of this natural arthritis treatment with European orthopedic surgeons and patients. Success of this trial would also...
validate the extension of the body of clinical evidence for NEM® from the United States to a European population. Therefore, a 2-month open-label study was conducted at six different clinical sites throughout Germany to evaluate the efficacy and tolerability of NEM® for the relief of the pain and discomfort associated with osteoarthritis of the knee and/or hip.

**Materials and Methods**

**Study design**

The study was conducted according to a prospective, multi-center, open label design and was conducted in Germany in accordance with the International Conference on Harmonization guideline for the principles of Good Clinical Practice (ICH E6) and the Declaration of Helsinki to ensure protection of human subjects. Patients provided their written informed consent to participate. Neither the clinical investigators nor the patients were blinded to treatment (open label design). Treatment consisted once daily orally of Atrosia® (Weber and Weber, GmbH and Co. KG, Germany) providing 500 mg of NEM® in vegetarian capsules that were stored in closed containers at ambient temperature. Clinic visits were scheduled for subjects at study initiation and at 60 days following the onset of treatment. Treatment compliance was checked at clinic visits by patient interview and by counting the number of unused doses of the study medications. Analgesics (i.e., acetaminophen) were allowed for rescue pain relief. However, subjects recorded the time and amount of analgesic taken in patient diaries so that overall analgesic use could be evaluated as part of the study.

**Patients**

All subjects 18 years of age or older who were seeking relief of mild to moderate pain due to osteoarthritis of the knee and/or hip were considered for enrollment in the study. In order to be eligible, subjects must have had moderate persistent pain in the knee and/or hip associated with osteoarthritis and must have had baseline scores within the range of 4-7 on the first three questions dealing with joint pain. Subjects that were currently taking analgesic medications or NSAIDs every day, currently taking glucosamine, chondroitin sulfate, pain. Subjects that were currently taking analgesic medications or within the range of 4-7 on the first three questions dealing with joint pain associated with osteoarthritis and must have had baseline scores that overall analgesic use could be evaluated as part of the study.

Results

Patient recruitment began in March 2012 at six clinical sites in Germany and the final follow-up was conducted in July 2012. A total of forty-four subjects between the ages of 32 and 95 were enrolled with treatment joint(s). Endpoints were then compared to pretreatment assessments. At the conclusion of the study, subjects were asked to provide a Patient’s Global Assessment of treatment efficacy (4 categories—very good/good/moderate/poor) and tolerability (same 4 categories). Clinical investigators were also asked to provide a Physician’s Global Assessment of treatment efficacy (5 categories—symptom-free/significant improvement/mild improvement/moderate improvement/unchanged/impaired).

**Adverse events**

A secondary objective of this study was to evaluate tolerability and any adverse reactions associated with supplementation with NEM®. The subject’s self-assessment diaries were reviewed and any discomfort or other adverse events were recorded and reported in accordance with applicable ICH Guidelines. Adverse events and serious adverse events were assessed by the clinical investigator at each study visit and followed until resolution, as necessary. Serious adverse events were required to be reported to the clinical monitor immediately.

**Statistical analysis**

As this was an open-label study, a simple single group sample size estimate [18] was performed for statistical power determination for a continuous variable. In previous trials with NEM® [6,7], the standard deviation for the study subjects for pain (within the inclusion range of this study) averaged 34.6%. We hoped to be able to detect a 1.5 point difference from baseline within the 10-point Likert scale. Thus a minimum of 43 subjects would need to be enrolled to have a 95% likelihood of detecting the expected improvement with a statistical power of 80%. Comparisons of demographic data from the six clinical sites were made with a Kruskal-Wallis test for multiple independent samples at baseline. Statistical significance was accepted at p<0.05. Post-baseline statistical analyses were done as repeated measures Analysis of Variance (rm-ANOVA) with a Greenhouse-Geisser correction. Items found to have statistical significance with rm-ANOVA were then compared using a Wilcoxon test for dependent samples. Statistical significance was accepted at p<0.05. Analysis of the primary outcome measure (the change from baseline in general pain levels) was conducted in the per protocol population. SPSS Statistics V19.0 was used for all statistical analyses [19].

**Results**

Patient recruitment began in March 2012 at six clinical sites in Germany and the final follow-up was conducted in July 2012. A total of forty-four subjects between the ages of 32 and 95 were enrolled with

Table 3: Mean values by question in an NEM-supplemented treatment group at baseline and 10, 30 and 60 days post-treatment.

osteoarthritis of the knee and/or hip. Of these subjects, twenty-seven (61%) were female and seventeen (39%) were male. The treated joints consisted of knee (39), hip (14), ankle (3), both either knee and hip (10), or both knee and ankle (2). Of the thirty-nine subjects with knee OA, sixteen (40.0%) had bilateral incidence. Of the fourteen subjects with hip OA, seven (50.0%) had bilateral incidence. Patient demographics are reported in Table 1. All forty-four subjects completed baseline evaluations. Thirty-seven (84%) of the forty-four subjects completed the two month study per the protocol. Compliance with the study treatment regimen was good.

Patient data was initially evaluated between sites to exclude site bias (not shown). As there were no abnormalities in these evaluations, the data were pooled for all subsequent analyses. A clinical comparison of valid subjects was carried out to obtain a mean baseline score for each of the ten questions from the patient questionnaire (Table 2). Statistical analysis of the primary outcome measure revealed that supplementation with NEM® produced a significant treatment response from baseline at 10 days (Q1-6 and Q9) (8.6% to 18.1% improvement) and at 30 and 60 days for all nine pain-related questions evaluated (22.4% to 35.6% improvement) (Table 3). Treatment response fell just shy of statistical significance at 10 days for Questions 7 and 8 (p=0.056 and p=0.064, respectively). Supplementation with NEM® produced a significant treatment response from baseline at 30 and 60 days for stiffness (Q10) (27.4% to 29.3% improvement). Greater than 50% of patients rated the efficacy of NEM® good or very good (Table 4) following 60 days of supplementation. Physicians also rated the treatment effective in subjects, with greater than 75% having moderate or significant improvement from baseline after 60 days (Table 5). For the 30 days prior to study commencement, patients consumed on average 7.0 ± 6.0 doses of acetaminophen. Analgesic use rebounded slightly to 3.59 ± 3.86 doses (per 30 days) by the end of the study at day 60. There were two adverse events reported during the study. One was a scratchy throat and was believed to be related to antibiotic use. The other was stomach discomfort which was believed to be related to the study material. There were no serious
Patients experienced relatively rapid (10 days) responses for pain-related questions with a mean response of approximately 14%. By the end of the follow-up period (60 days) the mean response for pain-related questions had more than doubled to approximately 33%. A brief responder analysis of the data provides a number of clinically relevant highlights. On average, nearly 1/4th of the subjects experienced a 30% improvement in pain-related questions within 10 days (Figure 1). And almost 20% of the study population experienced a 50% improvement in pain-related questions by the end of the study (60 days) (not shown). These results align well with results from previous clinical studies of NEM® that were conducted in the U.S. [6,7].

The safety profile for NEM® is also of significance as this is the fifth clinical trial to date in which there have been no reports of serious adverse events associated with treatment. No side effects from consuming NEM® have thus far been identified, excluding the obvious egg allergy concern. This is of obvious importance in a condition such as osteoarthritis that requires long-term treatment.

The trial had a limited initial enrollment (44 subjects), however there was a relatively low drop-out rate (16%) and good treatment compliance. As the trial was also open label, there is the obvious issue of the placebo effect. The inclusion of a placebo control would have provided greater clinical meaning, however it would have required a significantly larger study population.

Conclusions

With so many people suffering from osteoarthritis of the knee and hip in Western populations, it is important for patients to have treatment options that are both safe and effective. The reporting of the results from this six center, open label German clinical study demonstrates that NEM® brand eggshell membrane may be a viable treatment option for the management of osteoarthritis of the knee and/or hip in the broader European population. In this clinical study, NEM®, 500 mg taken once daily, significantly reduced pain, both rapidly (10 days) and continuously (60 days). It also showed clinically meaningful results from a brief responder analysis, demonstrating that a significant proportion of treated patients will benefit from NEM® supplementation.

Discussion

Joint and connective tissue disorders are quite common in Westernized countries [1,20] and result in significant costs, both financial [21] and quality-of-life [22], for those that suffer from the debilitating diseases. This open-label clinical trial was designed to evaluate the acceptability of this natural arthritis treatment with European orthopedic surgeons and patients and to validate the extension of the body of clinical evidence for NEM® from the United States to a European population through the evaluation of the efficacy, safety, and tolerability of NEM® brand eggshell membrane as a treatment option for osteoarthritis of the knee and/or hip. Results of the study indeed suggest that NEM® is both effective and safe for treating pain associated with osteoarthritis of the knee and/or hip in a European population.

adverse events reported during the study. The treatment was reported to be well tolerated by study participants with greater than 86% of patients rating NEM® tolerability as good or very good.

Effects of Natural Eggshell Membrane (NEM) on Cytokine Production in Cultures of Peripheral Blood Mononuclear Cells: Increased Suppression of Tumor Necrosis Factor-α Levels After In Vitro Digestion

Kathleen F. Benson, Kevin J. Ruff, and Gitte S. Jensen

1NIS Labs, Klamath Falls, Oregon, USA.
2ESM Technologies, LLC, Carthage, Missouri, USA.

ABSTRACT Tumor necrosis factor-α (TNF-α) plays an important role in inflammatory processes. This study examined the effects of natural eggshell membrane (NEM®) (ESM Technologies, LLC, Carthage, MO, USA) on interleukin (IL)-2, IL-4, IL-6, IL-10, interferon-γ (IFN-γ), and TNF-α cytokine production by 4-day peripheral blood mononuclear cell (PBMC) cultures exposed to serial dilutions of either an aqueous extract of natural eggshell membrane (NEM-AQ) or NEM subjected to in vitro digestion (NEM-IVD). The effects on cytokine production were also assessed in the presence of phytohemagglutinin (PHA) and pokeweed mitogen (PWM) where exposure to NEM-AQ resulted in reduced levels of proliferation and statistically significant effects on IL-6, IL-10, IFN-γ, and TNF-α cytokine production. NEM-AQ reduced levels of IL-6, IL-10, IFN-γ, and TNF-α in cultures exposed to PHA. In cultures containing PWM, NEM-AQ reduced production of IL-10 and at the highest dose tested increased IL-6 and decreased TNF-α cytokine levels. NEM-IVD, at the two lowest concentrations of product, significantly reduced TNF-α production by PBMC cultures exposed to PWM compared with the in vitro digest control or native NEM. Taken together, these results suggest that NEM-AQ can influence signaling events in response to the T cell-specific mitogen PHA as well as to the mitogen PWM that require cellular cross-talk and that these effects may be partially mediated through a reduction in level of the pro-inflammatory cytokine TNF-α. The suppression of TNF-α production in the presence of NEM-IVD is promising for the use of NEM as a consumable anti-inflammatory product.

INTRODUCTION

The main clinical manifestations of arthritis are inflammation, pain, and bone resorption. Chronic inflammation and bone loss are closely linked pathophysiological events. New scientific data point to a beneficial effect of blocking specific molecular interactions, which can reduce local arthritic symptoms even in the presence of ongoing chronic inflammation.1 The current mainstream medical treatments for arthritis involve pain management, anti-inflammatory drugs (nonsteroidal anti-inflammatory drugs, steroids, cyclooxygenase-2 inhibitors), and also exploration of chemokine receptor antagonists to stop cell migration into the inflamed areas.2–4 Part of the intensive pharmaceutical research efforts includes research on the interaction between osteoblasts and osteoclasts via the receptor activator of nuclear factor κB and its ligand. Receptor activator of nuclear factor κ is a hematopoietic surface receptor controlling osteoclastogenesis and calcium metabolism. Interference with these various pathways may also include arresting the maturation of phagocytic mononuclear cells into bone-resorbing cells, neutralizing pro-inflammatory cytokines, and blocking of matrix metalloproteinases. These mainstream treatments go far beyond a direct treatment of cells within the arthritic joints. They aim at reducing inflammation and inhibiting recruitment into the inflamed area of cells that contribute to disease processes, including bone resorption.

In contrast, nutraceutical products widely used for joint health include glucosamine, chondroitin, and hyaluronic acid, thus ignoring a multifaceted action of complex natural products. Even the spotlight on hyaluronic acid seems to limit its focus on replenishing the synovial fluid and on stimulating chondrocytes to produce more hyaluronic acid, thus ignoring the many complex ways that hyaluronic acid can modulate cells and their behavior.

Natural eggshell membrane (NEM®) (ESM Technologies, LLC, Carthage, MO, USA) is a novel dietary supplement that has been shown in several human trials to be a clinically effective treatment for pain and stiffness associated with joint and connective tissue disorders, particularly osteoarthritis.5,6 Eggshell membrane is primarily composed...
of fibrous proteins such as collagen type I. However, eggshell membranes have also been shown to contain glycosaminoglycans, such as dermatan sulfate, chondroitin sulfate, and hyaluronic acid, and sulfated glycoproteins, including hexosamines such as glucosamine. NEM contains up to about 5% of these various components, the unique combination of which may explain its biological activity. To further this understanding, a cytokine profile was determined from NEM-treated lymphocytes in cell culture.

The purpose of this study is to evaluate anti-inflammatory and immunomodulatory effects of NEM as well as its in vitro digest in a select series of human cell-based in vitro assays, in preparation for more comprehensive evaluations in vitro and in vivo.

MATERIALS AND METHODS

Reagents

Phosphate-buffered saline (PBS) (pH 7.4), RPMI-1640 culture medium, fetal calf serum, l-glutamine (200 mM), penicillin-streptomycin (100 × solution), glacial acetic acid, methanol, pepsin, pancreatin, bile salts, Histopaque 1077, and Histopaque 1119 were obtained from Sigma-Aldrich (St. Louis, MO, USA). The cytometric bead array (CBA) for human Th1/Th2 cytokine kit II was purchased from BD Biosciences (San Jose, CA, USA). All reagents for sodium dodecyl sulfate (SDS)–polyacrylamide gel electrophoresis (PAGE) and silver stain detection were obtained from Bio-Rad (Hercules, CA, USA) and included 4–15% Tris-HCl ready gels, Precision Plus dual color protein molecular weight standards, Laemmli buffer, 10×Tris/glycine/SDS buffer, silver stain concentrate, silver stain oxidizer, and silver stain developer. NEM was obtained from ESM Technologies, LLC.

Preparation of NEM for in vitro bioassays

The NEM powder was reconstituted in physiological saline and allowed to rehydrate for 1 hour at room temperature. Solids included insoluble calcium carbonate from eggshell and were removed by centrifugation at 900 g for 10 minutes. The liquid was filtered through a sterile cellulose acetate syringe filter (pore size, 0.22 μm). This filtrate corresponded to a stock solution of 100 g/L product (same concentration as the in vitro–digested NEM [NEM-IVD], described below). This aqueous preparation is designated NEM-AQ.

Preparation of an in vitro digest of NEM

The in vitro digestion of NEM was performed according to methods published in the literature11–13 (see also Fig. 4). In brief, 3.75 g of NEM powder was added to 30 mL of PBS and shaken at room temperature for 1 hour. Following the 1-hour incubation, the sample was spun at 900 g for 10 minutes, and the aqueous solution was removed from the solids and sterile-filtered with a cellulose acetate filter (pore size, 0.22 μm). HCl (1 M) was then added until the solution reached pH 2.0. Porcine pepsin was then added at a concentration of 1.3 mg/mL, and the sample was left at 37°C for 60 minutes with shaking (to simulate digestion in the stomach). Next, sodium bicarbonate (NaHCO3) was used to increase the pH of the solution to 5.8 (irreversibly inactivating pepsin), and pancreatin (0.175 mg/mL) and porcine bile salts (1.1 mg/mL) were added to simulate intestinal digestion. The pH was then adjusted to 6.5, and the mixture was left at 37°C for 1 hour. The final volume of the digest was adjusted with saline to give a final concentration of NEM of 100 g/L. Following this in vitro digestion, the sample was centrifuged through a 10-kDa cutoff filtration spin column to remove the enzymes from the digested product. This filtration step was necessary to avoid the presence of digestive enzymes in the downstream treatment of cells with product. This step also avoided the use of enzyme inhibitors that potentially could have direct effects on cell signaling in downstream cell-based assays. The liquid after in vitro digestion and size-exclusion filtration is designated NEM-IVD.

As the control, saline alone (negative control) was simultaneously subjected to the in vitro digestion protocol as described above. This was an important control to determine whether any bile salts or breakdown products from the enzymes themselves have biological activity. This PBS control is designated as PBS-IVD.

SDS-PAGE

SDS-PAGE was performed to compare crude NEM-AQ, NEM-IVD, and the PBS-IVD control. Samples were denatured by boiling for 3 minutes in 1×Laemmli buffer and separated by gel electrophoresis through a 4–15% polyacrylamide Tris-HCl gel using Protein Plus dual color molecular weight standards for reference. Silver staining was performed in order to visualize proteins, and an image of the stained gel was captured with a Canon (Lake Success, NY, USA) PowerShot SD430 digital camera.

Purification of peripheral blood mononuclear cells

Healthy human volunteers between the ages of 20 and 50 years served as blood donors after written informed consent was obtained, as approved by the Sky Lakes Medical (Klamath Falls, OR, USA) Center Institutional Review Board. Isolation of peripheral blood mononuclear cells (PBMCs) was performed as previously described14. PBMCs were used to establish lymphocyte cultures for the measurement of cytokine production.

Cytokine production by 4-day PBMC cultures

Freshly purified PBMCs were resuspended in RPMI 1640 medium supplemented with 10% fetal bovine serum, l-glutamine (2 mM), penicillin (100 U/mL), and streptomycin (100 mg/mL) at a density of 1×106/mL. Cells were cultured in the presence of 10-fold serial dilutions of NEM-AQ, NEM-IVD, or PBS-IVD in a series of triplicate wells containing a total volume of 200 μL. Three separate sets of
culture conditions were established: no mitogen, phytohemagglutinin (PHA), or pokeweed mitogen (PWM). The culture plate was incubated at 37°C in an atmosphere of 5% CO2 for 4 days, after which cells were transferred to a V-bottom plate and centrifuged. Cell supernatants were collected for cytokine measurement (described below). Determination of relative cell numbers in each culture well was performed by staining cells with the DNA dye CyQuant® (Invitrogen, Carlsbad, CA, USA) and measuring fluorescence measured with a Tecan (Durham, NC, USA) Spectraflour fluorescence plate reader. Samples were assayed in triplicate, and experiments were repeated three times with cells from three different donors.

Th1/Th2 cytokine profile

The cytokines interleukin (IL)-2, IL-4, IL-6, IL-10, tumor necrosis factor-α (TNF-α), and interferon-γ (IFN-γ) were quantified in the 4-day PBMC culture supernatants using a flow cytometry cytometric bead array (CBA) kit (CBA human Th1/Th2 cytokine kit II, BD Biosciences) that allowed the determination of the levels of all six cytokines simultaneously. Samples were tested in duplicate following the manufacturer’s instructions, data were acquired with a FACS Calibur™ flow cytometer (Becton-Dickinson, San Jose), and the analysis was performed with FlowJo software (TreeStar Inc., Ashland, OR, USA).

Statistical analysis

Statistical significance was tested using Student’s t test performed with the program Microsoft (Redmond, WA, USA) Excel. All P values were two-sided and were considered significant when P < .05. Only statistically significant P values are reported.

RESULTS

Lymphocyte proliferation assay

The lymphocyte proliferation assay evaluates whether a test product alters lymphocyte responsiveness to known signals such as mitogens. If any change in the proliferative response to known mitogens is seen in cells pretreated with test product, this is a good indication that the product has immunomodulatory effects and justifies further in-depth work on T and B lymphocyte signaling and activation.

Freshly purified human PBMCs were cultured for 4 days in the absence versus presence of serial dilutions of test products. Three parallel sets of cultures were established, where one tested the direct effect of test product on lymphocyte proliferation, and the two others examined the possible interference with response to the mitogen PHA or PWM. PHA produces a cleaner signal as it strictly induces proliferation of T lymphocytes, but PWM represents a more physiological signal mimicking the cellular interactions between monocytes/macrophages and T and B lymphocytes that occur in lymphoid tissue; therefore it is beneficial to test both in parallel. Positive controls included cells treated only with a mitogen in the absence of test product. No direct effects of product on lymphocyte proliferation were observed (data not shown). In the presence of PHA (Fig. 1A) and PWM (Fig. 1B), statistically significant decreases in proliferation of 30% and 15%, respectively, were seen with all three dilutions of NEM-AQ, indicating that pretreatment of PBMCs with NEM-AQ altered their response to subsequent signals.

Changes in Th1/Th2 cytokine levels

Supernatants were collected from 4-day cultures where PBMCs were exposed to test products in the absence versus presence of the mitogens PHA and PWM and analyzed for
the panel of Th1/Th2 cytokines IL-2, IL-4, IL-6, IL-10, IFN-γ, and TNF-α, using a CBA for flow cytometry. No statistically significant changes in cytokine production occurred in unstimulated cultures, whereas statistically significant changes in the cytokines IL-6, IL-10, IFN-γ, and TNF-α occurred in cultures that contained PHA (Fig. 2) or PWM (Fig. 3).

Cultures exposed to serial dilutions of NEM-AQ showed a biphasic response, including a strong increase of IL-6 at the highest dose tested (5 g/L) and a decrease at the two lowest concentrations of NEM-AQ tested. Decreases in IL-10 production were seen with all three doses of NEM-AQ in the presence of PHA. The cytokine IFN-γ levels decreased in a dose-dependent manner. This reduction in IFN-γ production was over 60% at the highest concentration of NEM-AQ tested. TNF-α production decreased in cultures exposed to serial dilutions of NEM-AQ. Statistically significant differences are indicated (*P < .05). The results shown are mean ± SD values from a representative of three separate lymphocyte proliferation cultures using cells from three different donors.

PWM were only seen at higher doses. The reduction in IFN-γ production in the presence of PHA was over 60% at the highest concentration of NEM-AQ tested. At the 0.05 g/L dose, a 35% reduction in TNF-α levels was seen, indicating a strong anti-inflammatory effect of NEM-AQ on TNF-α production at lower concentrations in the presence of the T-cell mitogen PHA.

In vitro digest

An in vitro digest as outlined in Figure 4 was performed on NEM-AQ as well as a saline control (PBS-IVD), and the resulting material was subjected to SDS-PAGE and silver stain detection in parallel with NEM-AQ. This analysis.
**FIG. 3.** Effects of NEM-AQ on production of the cytokines (A) IL-6, (B) IL-10, (C) IFN-γ, and (D) TNF-α by 4-day peripheral blood mononuclear cell cultures simultaneously exposed to PWM. Supernatants from 4-day peripheral blood mononuclear cell cultures were simultaneously assayed for the presence of cytokines using a flow cytometry–based assay. (A) IL-6 production in cultures exposed to serial dilutions of NEM-AQ showed a strong increase at the highest dose tested (5 g/L), whereas lower concentrations of NEM-AQ had no effect compared with IL-6 production in cultures exposed to PWM alone. (B) All three concentrations of NEM-AQ decreased IL-10 production in the presence of PWM about twofold. (C) Production of IFN-γ by 4-day cultures exposed to serial dilutions of NEM-AQ in the presence of PWM was affected differently depending on the concentration of NEM-AQ. These changes were not statistically significant. (D) In the presence of PWM, TNF-α production by 4-day cultures was decreased by the highest concentration of NEM-AQ, whereas lower concentrations of NEM-AQ had no effect on TNF-α production. Statistically significant differences are indicated (*P < .05). The results shown are mean ± SD values from a representative of three separate lymphocyte proliferation cultures using cells from three different donors.

**FIG. 4.** Diagram outlining the in vitro digestion procedure. Based on methods published in the literature,11-13 a stepwise process was performed that incorporated digestive enzymes derived from pig (porcine) and pH adjustments in order to mimic the digestive processes occurring in the stomach and small intestine. The final digested product was returned to physiological pH and subjected to size-exclusion centrifugation using a 10-kDa filtration column in order to remove the porcine enzymes. This process was performed with NEM-AQ, resulting in the product referred to as in vitro–digested NEM (NEM-IVD), as well as with phosphate-buffered saline (PBS), resulting in the product referred to as PBS-IVD.
showed a reduction of high-molecular-weight material in the NEM-IVD sample (Fig. 5) compared with the NEM-AQ sample, whereas the PBS-IVD sample did not show any detectable protein.

**Suppression of TNF-α production resulting from treatment of PBMCs with NEM-IVD**

In the context of the mitogen PWM, reflecting an in vitro model of the cellular collaborations in lymphoid tissue, the native NEM-AQ showed an anti-inflammatory effect only at the highest dose used, and the effect returned to baseline at the lower doses. In contrast, NEM-IVD showed significant anti-inflammatory properties across a wide dose range with respect to TNF-α production (Fig. 6). The in vitro--digested saline control (PBS-IVD) had some effects on PBMC culture proliferation and cytokine production that were different from those of saline alone, suggesting the presence of residual material derived from the in vitro digestion process. The effects seen at the two lower doses may be more relevant for predicting in vivo outcomes. The data shown are mean±SD values from a representative of three separate lymphocyte proliferation cultures using cells from three different donors.

**DISCUSSION**

Osteoarthritis is often considered a local problem centered on the specific target area where bone and joint degradation is seen, such as, for example, a knee. However, osteoarthritis is a systemic disease, involving immune dysregulation and altered cytokine profile (Fig. 7). In particular, T cells likely play an important role in the pathogenesis and progression of osteoarthritis. Osteoarthritis involves infiltrating monocytes producing TNF-α. It is also believed that peripheral blood leukocytes, which travel through the tissues of inflamed joints, are activated...
through exposure to locally produced mediators of inflammation (i.e., IL-1β, TNF-α, etc.). We were therefore interested in studying cytokine production in peripheral blood mixed cultures including monocytes. This was accomplished through an extended proliferation/cytokine assay, where both digested and undigested NEM preparations with appropriate controls were tested in serial dilutions in the presence and absence of mitogens. Two mitogens were tested in parallel: PHA, which is a T-cell mitogen that will induce T-cell proliferation, and PWM, which is a mitogen that requires the collaboration of T cells, B cells, and monocytes in the culture.

The significance of the data must be interpreted in light of the specificity of the culture conditions in the presence of the two separate mitogens, PHA and PWM, as well as the importance of the sequence in which stimulating agents were added. PWM is an aqueous extract from Phytolacca americana (pokeweed) that has mitogenic properties that involve mechanisms closely mimicking events in lymph nodes and other immune tissue where antigen presentation leads to co-stimulation and collaboration of multiple cell subsets. The mechanisms involve leukocyte aggregation. RNA synthesis precedes DNA synthesis by 24 hours, after which cell division begins, involving up to 60% of the peripheral blood lymphocyte fraction. The activation process involves T lymphocytes, B lymphocytes, and phagocytic mononuclear cells in tandem and generates both T cell– and B cell–derived cytokines, leading to generation of immunoglobulin-secreting plasma cells and a shift in CD45 isoform expression indicative of plasma cell differentiation. In contrast, an extract from Phaseolus vulgaris (red kidney bean) called PHA predominantly activates T lymphocytes, even though some B-cell activation can be seen as a result of the activated T cells triggering some B lymphocytes into proliferation. Therefore, these two mitogens were used as a method to shed light on events that are strictly T cell mediated versus events that require complex cellular collaboration (B cells and T cells).

The reduction of proliferation in NEM-treated cultures should not be seen as a suppression of a mitogenic response, but rather as evidence that NEM has leukocyte signaling properties of its own. The sequential addition of NEM first, followed by mitogens after 5 minutes, allowed compounds in NEM to engage signaling in target cells so when the mitogens were subsequently added the resultant signal was diminished.

Because NEM affected both PHA and PWM mitogenicity, but in different ways, this finding suggests specific mechanisms, including that NEM contains compounds directly able to modulate T-cell activation, and that NEM also has immune-modulating properties in the context of a more physiological activation process, such as in the PWM model of lymphocyte activation.

Cytokine production was affected in the cultures, with significant changes in three inflammatory cytokines: IL-6, IFN-γ, and TNF-α. It is interesting that this did not change when NEM was passed through the in vitro digestion protocol, except for TNF-α. The reduction in TNF-α production with NEM-IVD was seen at 100-fold lower doses than with undigested NEM. In the case of PWM stimulation, NEM-IVD showed anti-inflammatory properties by drastically reducing the production of TNF-α, in contrast to the mild increase in TNF-α production when cells were pretreated with NEM-AQ. Thus, the in vitro digestion potentiated the anti-inflammatory action of NEM, so that much lower doses of NEM-IVD were seen to produce similar effects as 25-fold higher doses of NEM-AQ. This is relevant for suggesting anti-inflammatory mechanisms in vivo after consumption of NEM and subsequent digestion in the stomach.

The dose–responses seen in the different assays were in several cases nonlinear. This may be attributed to several confounding factors associated with the highest dose, suggesting that the biological effects observed at lower doses should receive the most attention. It may be argued that the highest dose we used (5 g/L) exceeds a likely physiologically relevant dose. However, it may also be argued that this dose may be reached locally along the intestinal mucosa after consumption. We suggest that the highest dose (5 g/L) is quite high and that the biological responses seen at the two lower doses may be more relevant for predicting in vivo outcomes. There is also the possibility that calcium may have been an issue at the highest dose. NEM contains some calcium from unseparated eggshell, so for the most part this will be insoluble calcium carbonate. At the 5 g/L dose of NEM, the amount of calcium present may still be sufficient to interfere with cellular signaling. Further dilution of NEM may dilute calcium to insignificant levels. As it is therefore unlikely that calcium contributed to the different responses seen at the lowest dose, it cannot be completely ruled out as a potential mechanism of disturbing or abrogating cellular signaling at the highest dose used.

In the case of the TNF-α cytokine testing, the most interesting difference between the effects of NEM-AQ and NEM-IVD was the reduction in TNF-α production in the
presence of PWM that occurred with all three concentrations of NEM-IVD. These reductions in TNF-α production were strongest with the lowest doses of NEM-IVD, and this effect was opposite to that seen for NEM-AQ. Although the in vitro digestion procedure introduced compounds that were not completely removed by the size exclusion centrifugation step and that possessed bioactivity, the digestion process nevertheless increased the ability of NEM-AQ to reduce TNF-α production in 4-day PBMC cultures in the presence of PWM. The effect of NEM-IVD on TNF-α production in the presence of PWM was also different from the effect resulting from treatment of PBMC cultures with PBS-IVD and points to activities unique to the NEM-IVD product.

In particular, the result of NEM-AQ and NEM-IVD reducing TNF-α production is of interest in terms of identifying mechanisms of action pertaining to arthritis conditions because this cytokine is known to attract cell infiltration into arthritic joints and contribute to the inflammation within the joint.

Comparison of the effects of NEM-AQ and NEM-IVD on cytokine production by PBMC cultures reveals some differences that could not be entirely attributed to activities derived from the in vitro digestion process itself (such as enzyme breakdown products or residual bile salts that were not removed by the size exclusion centrifugation step). This unique effect of NEM-IVD with respect to TNF-α clearly warrants efforts to further investigate the effects of in vitro digestion on NEM. This is of particular importance as several biological TNF-α-inhibiting drugs have proven quite effective in treating arthritis but have been shown to have infrequent but often severe side effects. A treatment, such as NEM, that has immunomodulatory properties that are likely more diffuse could potentially avoid the unfortunate side effects of the currently available biological drugs.

Abstract We have found that a water-soluble alkaline-digested form of eggshell membrane (ASESM) can provide an extracellular matrix (ECM) environment for human dermal fibroblast cells (HDF) in vitro. Avian eggshell membrane (ESM) has a fibrous-meshwork structure and has long been utilized as a Chinese medicine for recovery from burn injuries and wounds in Asian countries. Therefore, ESM is expected to provide an excellent natural material for biomedical use. However, such applications have been hampered by the insolubility of ESM proteins. We have used a recently developed artificial cell membrane biointerface, 2-methacryloyloxyethyl phosphorylcholine polymer (PMBN) to immobilize ASEM proteins. The surface shows a fibrous structure under the atomic force microscope, and adhesion of HDF to ASEM is ASEM-dose-dependent. Quantitative mRNA analysis has revealed that the expression of type III collagen, matrix metalloproteinase-2, and decorin mRNAs is more than two-fold higher when HDF come into contact with a lower concentration of ASEM proteins than with a higher concentration.

dose ASESM proteins immobilized on PMBN surface. A particle-exclusion assay with fixed erythrocytes has visualized secreted water-binding molecules around the cells. Thus, HDF seems to possess an ECM environment on the newly designed PMBN-ASESM surface, and future applications of the ASESM-PMBN system for biomedical use should be of great interest.

**Introduction**

Extracellular matrices (ECM) not only serve a structural function providing support and strength to cells within tissues, but also determine critical cellular functions through cell-matrix interactions (Bruckner 2010). The unique architecture and characteristics of tissues and organs are determined by the ECM and the cells that produce it. ECM proteins can be classified into four general categories: collagens, structural glycoproteins, proteoglycans, and elastins (Tsang et al. 2010). In the dermis, heterotypic collagen fibrils containing mainly collagens I, III, and V are the major structural components responsible for its characteristic strength and resilience. Cell adhesion to ECM proteins through physical association with integrins is associated with intracellular signaling events and is critical for successful tissue regeneration (Grzesiak et al. 1997). Mechanical force increases the gene expression for collagen I and III in cycle-stretched cells obtained from ligament, such as anterior cruciate ligament cells (Kim et al. 2002) and bone-marrow-derived mesenchymal stroma cells (Zhang et al. 2008). ECM also plays important functional roles in interacting with numerous growth factors and signaling molecules to regulate cellular events such as cell adhesion, proliferation, migration, survival, and differentiation. Collagens are triple helical proteins that confer compressive and tensile strength to animal tissues and serve as anchors for cell adhesion through surface receptors.

Eggshell membrane (ESM), a functional equivalent of ECM in avian egg during development, is a double-layered insoluble sheet located between the eggshell and egg white and acts as a scaffold for biomineralization to fabricate the egg shell (Rose and Hincke 2009). The membrane is formed in the isthmus of the oviduct of the hen before shell mineralization and egg laying (Rose and Hincke 2009). ESM has a fibrous network mainly comprised of type I, V, and X collagens, glucosamine, desmosin, and hyaluronic acid (Ha et al. 2007; Osuoji 1971; Wong et al. 1984) and is cross-linked by lysyl oxidase (Harris et al. 1980). ESM also has antibacterial and antimicrobial activities to resist bacterial invasion (Ahlborn and Sheldon 2005) and thereby protect the developing embryo (Burley and Vadehra 1989). Recently, ESM-containing cosmetics and supplements have come onto the market worldwide, based on the evidence from traditional folk medicine in Asian countries. For more than four hundred years, ESM has been used to cure injuries, and the prescription appears in the pharmacopoeia of Chinese medicine, Bencao Gangmu. In Japan, Sumo wrestlers use ESM as a natural medicine for injuries. All this evidence suggests that ESM promotes wound healing. However, no molecular mechanism has been studied yet. Wound healing is a four-step sequential event including hemostasis, inflammation, proliferation, and remodeling (Diegelmann and Evans 2004). During these processes, tissue disruption has to be repaired and filled by ECM molecules (e.g., mainly collagen) deposited by dermal fibroblast cells.

In this study, we have aimed to construct a model system for the evaluation of ESM function on dermal fibroblast adhesion and the production of ECM components in vitro. Recently, the construction and modification of biomimetic surfaces has been targeted to support tissue-specific cell functions including adhesion, growth, differentiation, motility, and the expression of tissue-specific genes (von der Mark et al. 2010). We have used a novel artificial cell membrane biointerface, viz., a poly(2-methacryloyloxyethyl phosphorylcholine [MPC]-co-n-butyl methacrylate [BMA]-co-p-nitrophenyloxy carbonyl poly(oxyethylene) methacrylate [MEONP]) (PMBN; Konno et al. 2004) to immobilize alkaline water-miscible organic-solvent-hydrolyzed soluble eggshell membrane (ASESM) molecules. Phosphorylcholine group in the PMBN provides excellent biointerfaces, and these interfaces facilitate the suppression of nonspecific protein adsorption and stabilization of immobilized biomolecules (Watanabe and Ishihara 2007). BMA unit is hydropho-
bic polymer backbone, which can cover on the surface of substrates such as polystyrene tissue culture dish. MEONP unit contains active ester groups for the conjugation of the amino group of biomolecules via oxyethylene chain (Konno et al. 2004). Although accelerated cell growth of fibroblasts has been observed on an acid oxidized-pepsin digested ESM crosslinked to pepsin-solubilized collagen coat (Ino et al. 2006), our system has a unique advantage for the analysis of the molecular mechanism of ESM-fibroblast interaction. Since cells do not adhere at all to the conventional MPC polymer itself, unlike to collagen-coated dishes or polystyrene cell culture dishes, any specific and direct effects of ASES molecules on fibroblast adhesion can be tested.

Materials and methods

ASESM molecules

ASESM, which is hydrolyzed ESM digested in alkaline water-miscible organic solvent (EM PROTEIN-P), was purchased from Q.P. (Tokyo, Japan).

Microscopic ESM observation

Avian ESM was removed from eggshell, washed with water, and placed on the slide glass. The surface of the membrane was observed by means of a TCS-SP5 confocal microscope (Leica microsystems, Wetzlar, Germany) with a 488 argon laser.

Atomic force microscopy

The pyramidal-shaped silicon probe (OMCL-TR400PSA-1, 0.08 N/m) for atomic force microscopy (AFM) was purchased from Olympus (Tokyo, Japan). An MPC polymer such as PMBN was coated onto mica and dried. The mica was placed in a 12-well plate, and then 1 mg/ml or 30 mg/ml ASES was conjugated to it. AFM images of ASES-conjugated PMBN and non-conjugated control PMBN on mica were taken by using a Nanowizard II (JPK Instruments, Berlin, Germany) in intermittent contact mode in liquid.

Molecular weight estimation of ASES proteins by size-exclusion chromatography

The molecular weight of ASES proteins was estimated by size-exclusion chromatography on a Superose 6 HR 10/30 1.0 cm×30 cm size-exclusion column (GE Healthcare, USA) by using high performance liquid chromatography (Waters 640) with the following mobile phase: phosphate-buffered saline (PBS: 137 mM NaCl, 8.1 mM Na₂HPO₄·12 H₂O, 2.68 mM KCl, 1.47 mM KH₂PO₄), at a flow rate of 0.3 ml/min. Thyroglobulin (670 kDa), γ-globulin (158 kDa), ovalbumin (44 kDa), myoglobin (17 kDa), and Vitamin B₁₂ (1.35 kDa) in a gel-filtration standard (BioRad) were used to calibrate the column.

Cell culture

Human dermal fibroblasts (HDF) derived from infant skin were isolated as described previously (Aiba-Kojima et al. 2007). HDF were cultured with Dulbecco’s modified Eagle’s medium (Wako Pure Chemical Industries) containing 10% fetal bovine serum (Sigma-Aldrich), 0.1 mg/ml Kanamycin sulfate (Meiji Seika Kaisha), and a penicillin-streptomycin-neomycin (PSN) antibiotic mixture (1×; Gibco). HDF of passage number 8 were used in this study.

Synthesis of the PMBN

Methods for preparing PMBN were as previously described by Konno et al. (2004).

Dish coating

Polystyrene tissue culture (TC) dishes (35 mm; Falcon 353001, BD Biosciences) were coated with 0.2% PMBN, dried in an ethanol atmosphere, coated with 1 ml of various concentrations of ASES (0, 1, 5, 10, 30, 100 mg/ml Milli-Q ultrapure water; Millipore) at 4°C for 24 h, and then washed with PBS several times. Unreacted active ester units were blocked with 100 mg/ml glycine at room temperature for 2 h. Before cells were inoculated, the dishes were washed again with PBS. For control non-conjugated PMBN experiments, the active ester units in the PMBN coated surface were inactivated with glycine. PMBN dishes blocked with glycine were prepared. As another control experiment, collagen-coated dishes were prepared as follows: a TC dish was treated with 0.3 mg/ml collagen (from calf skin; Sigma, C9791) in hydrochloric acid solution (pH 3.0) for 5 min, air-dried, and rinsed with PBS. Cells were observed with an inverted microscope (Zeiss), and images were captured by a charge-coupled device camera (Orea, Hamamatsu, Japan). The brightness and contrast of images were adjusted by Adobe Photoshop Elements v. 6.0.

Quantitative gene expression analysis of HDF with or without ASESM

Total RNA from HDF cultured for 24 h was extracted by means of the High Pure RNA Isolation Kit (Roche Applied Science, Mannheim, Germany) according to the manufacturer’s protocol. First-strand cDNA was synthesized by using PrimeScript RT reagent kit (Perfect Real Time; Takara Bio). The primer and probe oligonucleotides for targeting human genes were designed by utilizing the Universal ProbeLibrary Assay Design Center (Roche Applied Science). All oligonucle-
cleotides were obtained from Nihon gene research laboratories (Sendai, Japan). Amplification of the housekeeping gene glyceraldehyde-3-phosphate dehydrogenase (GAPDH) mRNA, which served as a normalization standard, was carried out with GAPDH primers 5′-AGCCACATCGCTCA GACAC-3′ (sense) and 5′-GCCCAATACGACAAATCC-3′ (anti-sense). The gene-specific primers for COL3A1 were 5′-GGACCTCTTGGTGCTATAGGT-3′ (sense) and 5′- CGGTTCTACCTGATTTCCTCAT-3′ (anti-sense), for COL1A1 were 5′-GGGATTCCCTGGACCTAAAG-3′ (sense) and 5′-GGGACCCTGCTCTCCA-3′ (anti-sense), for matrix metalloproteinase 2 (MMP2) were 5′-GGAG GACCTTGCTTACCTAGC-3′ (sense) and 5′- GTCACGCAGCACACGATGC-3′ (anti-sense), for elastin were 5′-CGGGTCTACCTGATTCTCCAT-3′ (sense) and 5′-GGAAACACTCTGCTCTCCA-3′ (anti-sense), for matrix metalloproteinase 3 (MMP3) were 5′-GAGGTACACATGAAACCTCTCACA-3′ (sense) and 5′- TCAGGATAACATAGAAACATTTTGTGCTATAGGT-3′ (anti-sense), for hyaluronan synthetase 2 (HAS2) were 5′-CTCCTGGGACCCACACAG-3′ (sense) and 5′-TTCAGCTATT TGCTTGGGAAA-3′ (anti-sense), for hylauronan synthetase and elastin, were 5′-CATTGGGTATCCCCTCAAG-3′ (sense) and 5′- GTGGTGTAGGGCACCTCAGT-3′ (anti-sense), for decorin were 5′-GGGA CACTTTAAGAACCT GAAGAAC-3′ (sense) and 5′-CGTCTCAACCTCCAC CAAAGG-3′ (anti-sense), and for biglycan were 5′- CAGCCCGCAAACTGTAGC-3′ (sense) and 5′-GGCCAG CAGAGACACGAG-3′ (anti-sense). For the quantitative real-time polymerase chain reaction (PCR) analysis, an aliquot of 1 µl cDNA (25 ng total RNA equivalent) was added to 19 µl of the reaction mixture containing 1× Taqman Universal PCR Master Mix (Applied Biosystems), 900 nM forward/reverse primer, and 250 nM Universal ProbeLibrary probe (Roche). Standard GAPDH-based real-time PCR was performed by using the Applied Biosystems 7500 Fast Real-Time PCR System, and the following PCR cycle was employed: initial denaturation at 95°C for 20 s and then 40 cycles of amplification (denaturing at 95°C for 3 s and annealing and polymerization at 60°C for 30 s).

To analyze the ASES M dose-dependency of the ECM-related gene expression pattern, trendlines were calculated from five different trends (linear approximation, power approximation, exponential approximation, log approximation, polynomial approximation), so that its R-squared value was at or near 1.

**Immunofluorescence of HDF**

Cells were cultured on cover glasses (22 mm×22 mm, 0.12-0.17 mm thick, Matsunami Glass) in a 35-mm TC dish for 24 h. Cells were briefly washed with PBS and fixed at room temperature in Fix1 (4% parafomaldehyde, 2 mM MgCl2, and 2 mM EGTA in PBS) for 10 min. The cells were then washed several times with PBS and permeabilized with Fix2 (0.03% Triton X-100 in Fix1) for 10 min at room temperature. Fixed cells were washed several times with PBS and blocked in PBS containing 1% (w/v) bovine serum albumin and 0.02% sodium azide. Cells were incubated with goat polyclonal anti-procollagen type I antibody (SC-8783, Santa Cruz) overnight at 4°C, washed with PBS, followed by incubation with DyLight-488-conjugated anti-goat IgG (H&L) antibody (Rockland Immunochemicals for Research) for 1 h at room temperature. Images were taken by using a TCS-SP5 confocal microscope (Leica microsystems, Wetzlar, Germany). The brightness and contrast of images were adjusted by Adobe Photoshop Elements v. 6.0.

**Particle-exclusion assay**

To visualize the highly hydrated pericellular matrix around adhered HDF, the fluorescent version of the particle-exclusion assay using fixed sheep erythrocytes was performed. HDF (1.5×10⁴ cells/well) was inoculated into 24-well EZVIEW Glass Bottom Culture Plates LB (ASahi Glass). After 24 h, WGA (wheat germ agglutinin) Alexa Fluor 488 conjugate (W11261, Molecular probes) at 5 mg/ml in PBS was added to the culture plate for plasma membrane staining, incubated for 10 min at 37°C, and then washed off with PBS. Fixed sheep erythrocytes (5×10⁹; Inter-Cell Technologies) were reconstituted and pre-stained with Alexa-488-WGA in PBS, and then excess fluorescent reagent was washed out. Membrane-stained erythrocytes were added to the culture plate, and the cells were visualized with a LSM510 meta confocal microscope (Zeiss).

To estimate the size of the pericellular coat, the distance between the cell outline and the erythrocyte particle was measured (Simpson et al. 2009) by the LSM image browser (Zeiss).

**Results**

**Physical property of ASES M conjugated to PMBN**

The fibril meshwork of the natural avian ESM was observed by confocal microscopy (Fig. 1a). ESM is not a water-soluble material, because it is composed of highly cross-linked ECM molecules. Although commercially available ASES M powder is easy to dissolve to at least 40% (w/v) in ultra-pure water at room temperature, undigested and/or re-assembled fibril structure is postulated to remain in the ASES M because of its highly complex fibril architecture (Fig. 1a). The relative molecular weight of ASES M was analyzed by gel filtration, and its main mass was found to be about 12-14 kDa (Fig. 1b). Newly designed ASES M-PMBN was prepared by covalent bond formation between ASES M
proteins and PMBN, which has active ester groups (Konno et al. 2004). AFM analysis of ASESM-PMBN applied to mica showed a distinct fiber-like structure when 30 mg/ml ASESM was used for PMBN conjugation (Fig. 1e) but at not the lower concentration of ASESM (1 mg/ml; Fig. 1d). As a control, PMBN alone did not give any detectable structure (Fig. 1c). The typical 67-nm banding pattern of collagen fibrils was not observed in ASESM-PMBN, which is consistent with the result for ESM reported by Wong et al. (1984). ESM is a double-layered fibrous membrane consisting of cross-linked ECM proteins and is formed by lysyl oxidase secreted by the cells inside the hen oviduct during egg formation (Harris et al. 1980). A detailed structural analysis of ASESM fibrils on PMBN will be interesting, because this newly prepared biointerface provides a natural nano-scale fibrous scaffold for HDF as described below.

Adhesion of HDF to ASESM conjugated to PMBN

HDF adhesion to ASESM was initially tested in a plane TC dish. Either with or without ASESM pre-coating, cells adhered to the dish with no detectable difference (data not shown). To obtain a dish surface to which HDF adhered only when ASESM was present, a cytocompatible MPC polymer bearing active ester units, PMBN (Konno et al. 2004) was used, which can immobilize biomolecules (e.g., proteins, polysaccharides, and DNA) via covalent bond formation between the amino groups of target biomolecules and active ester units in the polymer under mild conditions. First, PMBN was coated onto a TC dish, and then various concentrations of ASESM (0, 1, 5, 10, 30, 100 mg/ml) were applied for conjugation (Fig. 2a-f). Non-reacted active ester groups in the PMBN were blocked by incubation with glycine, and then the dishes were washed with PBS before $8\times10^4$ HDF were seeded into them. After 24 h, cells were observed under the inverted microscope. We found that HDF had adhered to the ASESM-PMBN dishes (Fig. 2b-f) specifically, as compared with control glycine-conjugated PMBN dishes without ASESM (Fig. 2a). When more than 30 mg/ml ASESM was used for conjugation with the PMBN, the cell culture became semiconfluent (Fig. 2e, f), as in the dishes coated with type I collagen (Fig. 2g) and in untreated TC dishes (Fig. 2h). Interestingly, the mode of cell adhesion was ASESM dose-dependent when used with PMBN conjugation (Fig. 2b-f), but not with respect to the number of the cells inoculated. Notably, cells were relatively round and seemed not to be fully attached to the matrix formed by the lower doses of ASESM (1 mg, 5 mg/ml ASESM-PMBN in Fig. 2b, c, i) compared with the cells on control TC/collagen-coated dishes (Fig. 2h, l, m, o), and fully adhered to the matrix regardless of the cell density on the ASESM surface (adjusted by number of cells seeded). The morphology of HDF on ASESM at 10 mg/ml (Fig. 2j) showed an intermediate structure between the cells on ASESM at 5 mg/ml (Fig. 2i) and ASESM at 100 mg/ml (Fig. 2k) /control TC dish (Fig. 2l). These different cell adhesion modes, which various doses of ASESM were conjugated to the PMBN, the cells were extended and flat (Fig. 2f, k, n, p), similar to the cells on control TC/collagen-coated dishes (Fig. 2h, l, m, o), and fully adhered to the matrix regardless of the cell density on the ASESM surface (adjusted by number of cells seeded). The morphology of HDF on ASESM at 10 mg/ml (Fig. 2j) showed an intermediate structure between the cells on ASESM at 5 mg/ml (Fig. 2i) and ASESM at 100 mg/ml (Fig. 2k) /control TC dish (Fig. 2l). These different cell adhesion modes, which various doses of ASESM were used for PMBN conjugation, may reflect the surface structure (fibril plus or minus) as observed in AFM analysis (Fig. 1d, e).

ECM-related gene expression of HDF on ASESM conjugated to PMBN

Expression of the major ECM-related genes from HDF attached to different doses of the ASESM-conjugated matrix was examined by a standard quantitative real-time PCR protocol, and the gene expression pattern as a function of ASESM dose was analyzed by a curve fitting method (Fig. 3). The gene expression pattern of type III collagen (Fig. 3a), decorin (Fig. 3g), and MMP2 (also known as gelatinase A, Fig. 3e) at the various doses of ASESM was fitted with a power approximation curve, unlike the other genes: type I collagen (Fig. 3b), elastin (Fig. 3c), MMP3 (Fig. 3d), biglycan (Fig. 3h), and HAS2 (Fig. 3f). Interestingly, at the lower doses of ASESM conjugated to the MPC surface (1 mg/ml ASESM, the leftmost graph in each individual gene...
set in Fig. 3), the mRNA expression level of type III (Fig. 3a) but not type I collagen (Fig. 3b), MMP2 (Fig. 3e), and decorin (one of the proteoglycans that contains one chondroitin/dermatan sulfate GAG side-chain, Fig. 3g) was markedly increased by more than two-fold compared with control TC or collagen-coated dishes (Fig. 3a, e, g, inset). Other ECM-related genes such as type I collagen (Fig. 3b), elastin (Fig. 3c), MMP3/stromelysin-1 (Fig. 3d), and biglycan (Fig. 3h) showed similar mRNA expression levels as the control, with no ASESM dose-dependency. Expression of another ECM constituent, HAS2, which has a high molecular weight with unbranched polysaccharide extruded to the extracellular space, increased about three-fold depending on ASESM dose but was the same level as control (Fig. 3f). From these mRNA expression analyses, type III collagen, MMP2, HAS2, and decorin were found to be direct/indirect-response genes of HDF by ASESM proteins. Further study (e.g., time-course of gene and protein expression and identification of the related growth factors/cell signaling mechanism) will clarify the ASESM/ESM function toward HDF.

Visualization of ECM proteins and glycosaminoglycan in HDF: type I collagen and pericellular ECM

We also analyzed the ECM-related gene expression at the cellular level with or without ASESM in HDF by antibody detection of type I collagen and by particle-exclusion assay for detecting the highly hydrated ECM at the pericellular space (Fig. 4). HDF were grown on an ASESM surface (Fig. 4c, d), on a surface coated with type I collagen (Fig. 4b), or on glass (Fig. 4a) and fixed. Indirect immunofluorescence detection of procollagen type I was performed. The antibody recognizes the procollagen in the endoplasmic reticulum. The localization pattern was similar between the cells on the type I collagen coat (Fig. 4b) and on higher doses of the ASESM conjugated surface (Fig. 4c, d) consistent with the result as shown in Fig. 2o, p.

ECM-related glycosaminoglycan (GAG), such as decorin and hyaluronan (gene product of HAS2), is responsible for various cellular function including adhesion and wound healing (Laurent and Fraser 1992). GAG is a highly hydrophilic molecule that exists on the cell surface and binds a large amount of water around the cell. Visualization of such a pericellular coat can be achieved by the reported particle-exclusion assays on fixed erythrocytes for hyaluronan detection (Itano et al. 1999; Fig. 4e-h). The distance from the cell surface to the excluded area is similar between low and high doses of ASESM. Although the HAS2 expression was relatively low for HDF on lower dose of ASESM surface (Fig. 3f), HDF appeared to secrete similar amounts of pericellular coat as on other culture surfaces. A relatively clear exclusion pattern was seen for the cells on a lower dose of ASESM surface (Fig. 4f). This might be correlated to the higher decorin mRNA expression (Fig. 3g),
Fig. 3 Relative gene expressions of HDF on various amounts of ASESМ (1, 5, 10, 30, 100 mg/ml) conjugated to PMBN as normalized with glyceraldehyde-3-phosphate dehydrogenase: type III collagen (COL3; a), COL1 (b), elastin (c), matrix metalloproteinase (MMP3; d), MMP2 (e), hyaluronan synthetase 2 (f), decorin (g), and biglycan (h). The assay was carried out on triplicate samples with 500 ng total RNA recovered from each dish. The data are presented as means±SD (arb. units arbitrary units). The fitted curves are as described. Insets Relative gene expressions in HDF on either dishes coated with type I collagen (COL) or untreated tissue culture dishes (TC). Horizontal axis in each graph represents various concentrations of ASESМ conjugated to PMBN (mg/ml).

Fig. 4 Visualization of type I collagen protein and particle-exclusion assay on HDF. Cells were grown on glass (a), a collagen coat (b), 30 mg/ml ASESМ-PMBN coat (c), or 100 mg/ml ASESМ-PMBN coat (d). Bar 20 μm. Highly hydrated ECM-related glycosaminoglycan coat around HDF grown on glass (e), or on 1 mg/ml (f), 10 mg/ml (g), or 100 mg/ml (h) ASESМ-PMBN coat. Bars 20 μm.
and/or the distinct motility of the cells (Evanko et al. 1999) might be responsible for this observation as previously described in Fig. 3. The distance from cell surface to excluded area is not different between low and high doses of ASESM. These data show that HDF on the ASESM surface secrete a pericellular coat, including hyaluronan, as on other culture surfaces.

Discussion

We have developed a new in vitro system to study ESM function with respect to HDF adhesion by applying the PMBN. ESM is a readily available natural biomaterial everywhere in the world and can be used in the biomedical, nutritional, and cosmetic fields. The membrane is a highly cross-linked meshwork mainly consisting of ECM molecules such as collagens, proteoglycans, and GAG. A commercially available, alkaline-hydrolyzed version of ESM, ASESM, has been used in this study. Based on AFM analysis, ASESM has been found to adopt a distinct fibril structure compared with the original ESM, either because hydrolysis-tolerating fibers remain and/or hydrolyzed ECM are reassembled de novo on PMBN. An analysis of this assembly process will be interesting from two different viewpoints: (1) in order to understand the HDF adhesion mode and to develop a new biointerface by using ESM and thereby providing different cell adhesion and gene expression properties, and (2) in order to understand an as yet unknown eggshell/shell membrane formation mechanism inside the oviduct of the hen, a mechanism expected to provide hints for designing new biomaterials.

In this study, specific dish surface ASESM conjugated to PMBN was prepared and tested for HDF adhesion. Cells adhere to ASESM on PMBN specifically (Fig. 5b, c) but not to glycine-blocked PMBN (Fig. 5a), and ECM genes are expressed. The most notable finding from our study is that ECM gene expression is significantly altered simply by the cell density and microenvironment of the cells and suggests the following two important points: first, the specific dish surface of ASESM conjugated to PMBN provides a useful in vitro experimental culture system mimicking the actual cell environment inside our living human body; second, the present study provides the first mechanistic insight into the reason that ESM encourages scarless wound healing, as has been known for many years in Asian countries.

Fibroblasts are generally and widely used cultured cells in the field of biological sciences and almost all reported experiments are performed under confluent cell conditions with no thoughts of the in vivo situation. If we look at any of the histological images from tissue sections or the in vivo images of dermis, tendon, and joints in our body, we can readily notice that fibroblasts are dispersed and not "confluent". In spite of the importance of ECM, few studies have investigated tissue origin-dependent cell-ECM interactions or cell-cell interactions in vivo. To visualize such interactions, a histological approach is commonly used, but the dynamic response of the cells to the environments and the modulation of the cytoskeleton and ECM cannot be studied. In the case of recently developed induced pluripotent stem cells (iPS; Takahashi and Yamanaka 2006), robust and intensive studies have been performed world-wide, and a quick shift from basic research to practical applications has been brought about, because such investigations are based on an easily controllable, in vitro cell culture technology. With in vitro systems, cells that survive in various regions of the body (tissue) can be analyzed not only under various nutritional factor conditions, but also with regard to the stiffness of their substrate (Discher et al. 2005). Three-dimensional culture systems are certainly more preferable than two-dimensional systems, because

![Fig. 5 Characteristic features of the ASESM-PMBN system. a Without ASESM, cells do not adhere to PMBN, because unreacted active ester groups were blocked with glycine. b Low dose of ASESM conjugated to PMBN provides early wound healing model. c High dose of ASESM conjugated to PMBN provides a more stretched and rigid environment](image-url)
they more closely resemble in vivo conditions, and the mechanical character of ECM and the change of gene expression induced by an environmental cue can be detected (von der Mark et al. 2010). However, complex three-dimensional systems are not always necessary for the direct analysis of the cells responding to a specific biomaterial, as described in this study. Gene expression supplies the ECM environment to HDF, and this may partially explain the biomedical function of ESM for the healing of skin injuries (wound healing). Indeed, Rinn et al. (2008) have demonstrated that dermal fibroblasts are developmentally regulated by particular HOX genes dependent on the different regions in the body. Fibroblasts originating from other skin regions of the body or connective tissues might respond to ASESM differently from those taken from the auricle as used in this study. Our newly developed experimental system might be suitable for investigating site-specific cell response in general. Further studies should clarify the complex biological mechanism regarding the association of HDF and other adhesive cells to ASESM, by adding/subtracting the involved factors in a step-by-step fashion.

We have studied mRNA expression by the quantitative real-time PCR analysis of HDF grown on ASESM. ECM-related genes, which might contribute to maintaining the extracellular environment for healthy dermis, such as those for type III collagen (Vitellaro-Zuccharello et al. 1992), MMP2 (Kahari and Saarialho-Kere 1997), and decorin (Nomura 2006), show a more than two-fold higher expression when cells are grown at a lower dose of ASESM on a surface than when they are cultured on a control dish surface. In the contrast, HAS2 expression is high at a higher dose of ASESM on the surface.

Cutaneous wound healing is a dynamic process that involves the coordinated and sequential deposition of ECM, leading to the formation of a scar. In this study, during the culture of HDF on ASESM for just 24 h, an interesting pattern of gene expression of ECM components including collagen, proteoglycans and hyaluronan and their proteases has been observed, as a function of the applied ASESM quantity. This ASESM dose-dependency seems to be consistent with the temporal expression pattern of ECM molecules during sequential wound healing process. The ECM expression pattern in low-dose ASESM is similar to the early phase, whereas that at a high dose resembles the late phase of wound healing. To analyze the ASESM dose-dependency of ECM-related gene expression patterns, a trendline can be added to the graph by a curve fitting method (Fig. 3). Type III collagen, decorin, and MMP2 are strongly expressed in the early phase of wound healing. In our study, the expression pattern of these three genes have been fitted into a downward power approximation toward the high ASESM dose, whereas other genes have been fitted by the binomial equation, exponential equation, or log approximation. Interestingly, the ASESM dose-dependent increment of HAS2 mRNA fits an upward exponential equation. Although we have not checked the gene expression at a time point other than 24 h, the level of mRNA expression of these wound-healing-related genes at different ASESM concentrations matches the gene expression during the course of sequential events of cutaneous wound healing in vivo; lower ASESM providing an environment similar to the early steps, and higher ASESM for late steps. Based on our AFM analysis (Fig. 1c-e), ASESM seems to adopt a distinct fibril structure depending on the concentration of ASESM applied to PMBN for conjugation, either because the hydrolysis-tolerating fibers remain and/or hydrolyzed ECM are reassembled de novo on PMBN.

Since mutations for both type III (Liu et al. 1997) collagen and decorin (Jarvelainen et al. 2006) are not lethal in the mouse, these genes are not essential for survival but are important for providing a soft environment within tissues and play roles in modulating the ECM environment, being responsible for elastic young skin, for human health, and for body maintenance in aged people. The major function of type III collagen is associated with the fibrogenesis of type I collagen (Liu et al. 1997). Type III collagen is a fibrillar forming collagen comprising three alpha-1 (III) chains and is expressed in early embryos and throughout embryogenesis. In the adult, type III collagen is a component of the ECM in a variety of internal organs and skin. Patients with type IV Ehlers–Danlos syndrome, a genetic disorder associated with fragile blood vessels and skin, often carry mutations in the COL3A1 gene encoding for type III procollagen (Kontusaari et al. 1990; Kuivaniemi et al. 1995; Prockop and Kivirikko 1984). Type III collagen is an important for the development of skin and the cardiovascular system and for maintaining the normal physiological functions of these organs in adult life (Olsen 1995). In addition, type III collagen is known to be prominent at sites of healing and repair in skin and other tissues (Wu et al. 2010). Type III collagen is the major constituent of early granulation and scar tissue, whereas only a small amount of type I collagen is present in this early phase of healing (Betz et al. 1993; El Sherif et al. 2006). On the other hand, type I collagen is a major fibrous component in connective tissue. During the wound healing process, type I collagen accumulates in granulation tissue (Kanzler et al. 1986). Because the expression of type III collagen is usually greater than the expression of type I collagen during early wound healing, the lower ASESM-PMBN in vitro system might provide an ECM environment similar to that of the early phase of wound healing.

Decorin belongs to the small leucine-rich proteoglycans (SLRPs), which are expected to play important functions in tissue assembly. Danielson et al. (1997) have reported that mice possessing a targeted disruption of the decorin gene
are viable but have fragile skin with markedly reduced tensile strength. Since the repair of wound healing is delayed in the decorin-knockout mouse, decorin proteoglycan is necessary for the wound healing process (Jarvelainen et al. 2006). In keloid scars seen in deregulated wound healing, decorin expression is downregulated, whereas syndecan-2 and fibroblast growth factor-2 (FGF-2) are upregulated (Mukhopadhyay et al. 2010). In addition, the activation of extracellular signal-regulated kinase-1 (ERK1) and ERK2 and the lower expression of decorin are found in the fibroblasts of the dermal region in keloids (Meenakshi et al. 2009). On the other hand, the overexpression of the decorin gene in human corneal fibroblasts inhibits transforming growth factor-β (TGF-β)-induced fibrosis and myofibroblast formation (Mohan et al. 2010). These reports suggest that decorin has an antifibrotic effect in an aberrant wound healing process leading to keloid scars.

MMPs play a role in various aspects of cutaneous biology and pathology, e.g., in wound repair. MMP2 is expressed in the early phase (7th day) of wound healing (Jansen et al. 2007). MMP2 expression is high in low-dose ASESM in our in vitro system. MMP2 degrades various ECM molecules, such as collagen types I, IV, V, VII, and X, gelatin, fibronectin, tenascin, fibrillin, osteonectin, entactin, aggrecan, vitronectin, and decorin (Kerkela and Saarialho-Kere 2003) and is activated by dermatan sulfate (Isnard et al. 2003). Since dermatan sulfate is reported to be one of the components of ESM (Osuoji 1971), it is also present in our ASESM system and might contributed to MMP2 activation. MMP2 seems to be a key molecule for tissue remodeling, as demonstrated by Tholozan et al. (2007) who have shown that lens epithelial cells produce several MMPs including MMP2, which releases FGF-2 from the lens capsule. In this system, the recently proposed ECM reservoir hypothesis has been established, because the ECM itself can act as a reservoir for growth and survival factors that are released via the action of various MMPs such as MMP2 (Tholozan et al. 2007). Thus, lower density cell culture on low ASESM might provide a good environment for wound healing without leading to keloid scar formation during tissue regeneration.

In vivo, fibroblast cells are located separated from each other, which differs from the situation for keratinocytes in the epidermis. As described above, collagen type III, decorin, and MMP2 play an important role in wound healing, type I collagen fibrogenesis, and the maintenance and turnover of the ECM environment during skin damage. In this study, sparsely located HDF show an unextended-shape on a low-dose ASESM matrix, whereas the mRNA expression levels of type III collagen, MMP2, and decorin markedly increase more than two-fold compared with those of cells grown on control TC or collagen-coated dishes. The proteins encoded by these ECM genes are key molecules for remodeling of ECM in wounded and developing dermis and contribute to keeping the skin healthy. However, the precise mechanisms of their involvement are largely unknown.

HDF express collagen type III, MMP2, and decorin mRNA at a higher level on a low dose of ASESM, but the levels of collagen type I, elastin, MMP3, and biglycan are not significantly altered. Biglycan belongs to the group of small leucine-rich proteoglycans, as does decorin, and decorates collagen during fibrogenesis (Corsi et al. 2002). Decorin and biglycan expression patterns are reported to be differentially regulated during wound healing. In dermal fibroblast cultures, decorin expression is stimulated by glycyl-histidyl-lsine-Cu²⁺, which is a tripeptide isolated from human plasma and a potent activator of wound healing. In contrast, biglycan expression is not modified (Pickart and Thaler 1973). In addition, the inactivation of the decorin gene by homologous recombination (Danielson et al. 1997; Xu et al. 1998), but not that of biglycan (Simeon et al. 2000), is associated with a fragile skin collagen network. A previous study has also revealed few changes occur with regard to biglycan expression through 1–49 days of the wound healing process in pig (Wang et al. 2000). Thus, we can reasonably conclude that different regulatory mechanism are also involved in the patterns of expression of decorin and biglycan in our system, despite both belonging to the small leucine-rich proteoglycans.

Elastin, which constitutes elastic fibers in the dermis, blood vessel, and lung (Rosenbloom et al. 1993), did not change its expression level related to ASESM quantity in this study. However, a relatively low expression level was observed under lower dose ASESM conditions. A previous study has indicated that elastin expression increases during the early phase of wound healing (Quaglino et al. 1990). Basic fibroblastic growth factor has been reported to be of importance in the regulation of ECM gene expression, such as the decrease of elastin expression (Debelle and Tamburro 1999) but increase of type III collagen and decorin (Li et al. 2009; Tan et al. 1993). Although growth factors/cytokines were not measured in this study, the dose-dependent change of ECM mRNA may well reflect the ECM-cytokine relationship during wound healing described in previous reports.

The expression pattern of MMP3 mRNA at the different ASESM concentrations are a mirror image of the pattern of elastin expression. MMP3 is secreted mainly by macrophages and fibroblast cells (Saarialho-Kere et al. 1994; Welgus et al. 1990; Wilhelm et al. 1987) and digest a broad range of ECM molecules, such as type I collagen, various proteoglycans, and others (ColIII, IV, V, VII, IX, and X, elastin, fibronectin, fibrillin, fibrinogen, gelatin, aggrecan, plasmin, kallikrein, chymase, LN-1, nidogen, vitronectin, osteonectin, decorin; Kerkela and Saarialho-Kere 2003), as substrates. The higher MMP3 mRNA expression either at
low ASESM (ASESM at 1, 5, 10 mg/ml) or high ASESM (ASESM at 100 mg/ml) might indicate that ECM turnover is high under these conditions. Delayed and incomplete wound healing is observed in the MMP3-knockout mouse resulting from insufficient myofibroblast migration or differentiation. Therefore, MMP3 function is important for proper wound healing, and our ASESM system provides the necessary environment.

Interestingly, a large difference has been noted in HDF cell shape between low- and high-dose ASESM (Figs. 2, 5b, c), suggesting that different actin dynamics and related signal transduction mechanisms are involved in the two states. Hyaluronan expression level seems to change in relation to the cellular and extracellular metabolism and to the immune system through actin dynamics (Boraldi et al. 2003; Stem 2003). Particle-exclusion assay in this study shows water-binding ECM surrounding HDF cells grown on both low and high dose ASESM. The distance of the water-binding ECM from the cell surface to the excluded erythrocyte is similar between low and high ASESM. This data suggest that HDF on the ASESM surface secretes enough pericellular coat, including GAG-bound proteoglycan and hyaluronan, at a low dose of ASESM and at a high dose of ASESM. The pericellular hyaluronan coat requires TGF-β expression (Simpson et al. 2009). The differentiation of fibroblasts to myofibroblasts during wound healing needs the expression of epidermal growth factor receptor and ERK1/2, and smooth-muscle α-actin, which is a marker of myofibroblasts (Simpson et al. 2009). Type III collagen has an important role in wound healing, because the expression of type III collagen increases early during wound healing processes (Liu et al. 1995). Human fibroblasts with mutations in the COL5A1 and COL3A1 genes do not organize collagens and fibronectin in the ECM, down-regulate α2β1 integrin, and recruit αvβ3 instead of α5β1 integrin (Zoppie et al. 2004). The αvβ3 receptor (vitronectin receptor) and the α5β1 receptor (fibronectin receptor) have been shown to be important in myofibroblast differentiation (Lygoe et al. 2007).

Mice deficient in type III collagen have an increased myofibroblast density in the wound granulation tissue, as evidenced by the increased expression of the myofibroblast marker, smooth-muscle α-actin, and wounds in such mice have significantly more scar tissue area compared with that of wild-type mice (Volk et al. 2011). In our study, HDF cultured on the low-dose ASESM environment induce a cytoskeletal rearrangement and change the expression of ECM, especially type III collagen, by affecting the interaction with integrin. We hypothesize that the newly designed PMBN-ASESM biointerface mimicks the microenvironment of both early and late remodeling in the wound healing process.

The inductive mechanism of these highly expressed genes (type III collagen, decorin, and MMP2) in HDF on the low dose of ASESM seems to be related to the cell shape, cellular environment, cell-cell interaction (low or high cell density), and ECM components or its structure. Because the high dose of ASESM does not activate these three genes, regardless of the cell density, we suggest that the particular ECM environment that is mediated by the low ASESM dose plays a pivotal role for the observed cell adhesion mode and therefore affects the gene expression pattern. ASESM, the hydrolyzed material of ESM, might contain the ECM-related molecules and MMPs as regulatory factors. We hypothesize that HDF secrete exactly the same or similar ECM proteins to those of the surrounding ECM, because fibroblasts are known to be responsive to various signals (Discher et al. 2005). Cells express the corresponding genes in response to their surrounding environment and to environmental stimuli (mechanical force or UV stress, etc.). Cells and ECM interact with each other and adapt to their environment. If the environment of the cells is adequate, they can maintain the optimal condition for their survival. Mesenchymal stem cells retain their pluripotency providing that the surrounding environment remains suitable for stem cells.

In this study, the three genes (type III collagen, decorin, and MMP2) that are expressed in younger skin or early wound healing process are highly expressed by HDF on low doses of ASESM. This probably occurs because the required structure pre-exists or is assembled de novo on PMBN.

ESM might contain almost all ECMs and ECM-regulatory gene products that have been evolutionally conserved in avians. Previous studies have shown that ESMs have a fibrous network mainly comprised of type I, V, and X collagen, glucosamine, desmosin, hyaluronic acid (Ha et al. 2007; Osuoji 1971; Wong et al. 1984); because these molecules are cross-linked by lysyl oxidase (Harris et al. 1980), each component in ESMs cannot exist independently. In the low concentration solution (low-dose ASESM), hydrophilic small molecules that are produced by the moderately alkaline hydrolyzed ESM might be assembled in such a manner that a large amount of water surrounds it, thereby creating an ECM environment that mimicks younger skin. In contrast, the high concentration of ASESM (high-dose ASESM) might induce the self-assembly of the ASESM components, such as the more hydrophobic ECM molecules (collagens) that relatively easily exclude water.

Such a self-assembly of macromolecules (ECM-related fibrils) might be involved during embryonic development and wound healing process in the animal body. By using a novel combination of a natural (ESM) and artificial cell membrane interface (PMBN), ECM components in ESM might be able to self-assemble differently and provide a distinct ECM environment depending on the ASESM concentration. Thus, the cells adhere to the respective environment and express the observed ECM components. The ASESM-PMBN system in this study should be
applicable in various mechanistic studies of biological processes, such as wound healing, embryonic development, acquisition of tissue specificity, evolution and morphogenesis, at the molecular level.

In conclusion, ASES have been stably conjugated to PMBN and provides an ECM environment for HDF. ESM also acts as a scaffold for eggshell mineralization and might have properties for capturing various factors and molecules that are necessary for avian embryonic development. Recently, a clinical evaluation of natural ESM has also reported joint and muscle pain relief (Ruff et al. 2009a, b). Although the immobilization of joint joints induces articular contracture associated with sequential changes of disordered ECM alignment, increased collagen glycation with pentosidine, and decreased cell numbers (Lee et al. 2010), the possible in vivo application of ASES might not only stabilize connective tissues such as joints, but also stimulate ECM production therein. Further study of the ASES-PMBN system with respect not only to skin wound healing, but also to the treatment of joint pain such as osteoarthritis should be considered, as MPC polymer has been shown to improve the surface grafting of artificial joints dramatically (Moro et al. 2004) and is under clinical trial awaiting biomedical use. In addition, our ASES-PMBN system provides a rare experimental model for studying a mutually dynamic biological process in vitro: the cell responds to the surrounding microenvironment by secreting an ECM, and vice versa, the environment stimulates the cell.

Acknowledgements We appreciate the valuable comments of the reviewers. We thank the Radio Isotope Center and Center for NanoBio Integration (CNBI), The University of Tokyo for the use of analytical equipment, and we are grateful to Prof. Yoshihiko Nakamura at The University of Tokyo for administration of the “Cell to Body Dynamics Project”, which included this ESM cooperative project.
